Title: On the stability of unsaturated natural slopes

Occasionally, the classical stability calculation of a stable natural slope yields a safety factor that is less than one. This suggests that the slope should have already failed. How can this be explained? Are we missing something in our calculations?

Besides introducing the basic concepts related to the mechanical behavior of unsaturated soil, the project discusses a simple analysis method to include partial saturation effects in slope stability calculations. The employed hydraulic boundary conditions in the project resemble possible scenarios of environmental loadings (evaporation, rainfall, etc.). The project language is English.
